Note: This lecture is adapted from work by Grant McDermott on **vector-based** spatial analysis – check it for stuff like this. We will not cover **raster-based** spatial analysis, although this is an equally important subject. Here is a link to it a lecture on it by Grant McDermott. There are further resources below. Rasters are used to make satellite images, relief maps, etc.

Working through interactively

I heavily suggest that you work through this lecture interactively, you'll get the most out of it if you're able to run the code chunks yourself. There are two ways to do this:

- 1. **GitHub Codespaces:** This is the easiest way to get started. Just click on the green "Code" button on the top right of the repository and select "Open with Codespaces". This will open an RStudio environment in your browser, with all the necessary packages pre-installed.
- 2. Fork the repository and clone it: If you have not yet forked these materials, you can do so by clicking the "Fork" button on the top right of the repository. Once you have your own fork, you can clone it to your local machine, then navigate within it.

Once you have access to these notes and your R environment setup, navigate to the directory lectures/08-spatial-analysis and open the 08-spatial.Rmd file. You can then start running the code chunks.

3. **Run on your own computer**: Everything here is self-contained. Any installations are included in the code chunks, so you can run everything from start to finish with copy-and-paste.

Requirements

External libraries (requirements vary by OS)

We're going to be doing all our spatial analysis and plotting today in R. Behind the scenes, R provides bindings to powerful open-source GIS libraries. These include the Geospatial Data Abstraction Library (GDAL) and Interface to Geometry Engine Open Source (GEOS) API suite, as well as access to projection and transformation operations from the PROJ library. You needn't worry about all this, but for the fact that you *may* need to install some of these external libraries first. The requirements vary by OS:

- Linux: Requirements vary by distribution. See here.
- **Mac:** You should be fine to proceed directly to the R packages installation below. An unlikely exception is if you've configured R to install packages from source; in which case see here.
- Windows: Same as Mac, you should be good to go unless you're installing from source. In which case, see here.

R packages

- New: sf, lwgeom, maps, mapdata, spData, tigris, leaflet, mapview, tmap, tmaptools, nngeo
- Already used: tidyverse, data.table, hrbrthemes, tidycensus

Truth be told, you only need a handful of the above libraries to do 95% of the spatial work that you're likely to encounter. But R's spatial ecosystem and support is extremely rich, so I cover a number of specific use-cases in this lecture. Run the following code chunk to install (if necessary) and load everything.

```
## Load and install the packages that we'll be using today
if (!require("pacman")) install.packages("pacman")
pacman::p_load(sf, tidyverse, data.table, hrbrthemes, lwgeom, rnaturalearth, maps, mapdata, spData, tig
## My preferred ggplot2 plotting theme (optional)
theme_set(theme_minimal())
```

Census API key

Finally, we'll be accessing some data from the US Census Bureau through the tidycensus package. This will require a Census API key, which you can request here. Once that's done, you can set it using the tidycensus::census_api_key() function. I recommend using the "install = TRUE" option to save your key for future usage. See the function's help file for more information.

tidycensus::census_api_key("PLACE_YOUR_API_KEY_HERE", install = TRUE)

Also tell the tigris package to automatically cache its results to save on repeated downloading. I recommend adding this line to your \sim /.Rprofile file so that caching is automatically enabled for future sessions. A quick way to do that is with the usethis::edit_r_profile() function.

```
options(tigris_use_cache=TRUE)
```

Data Downloads

Today we'll be mapping the Opportunity Atlas datasets at the county level. Specifically, we're going to map the average income percentile of children born to parents at different percentiles.

You can manually download or automate the download using download.file. download.file has a default "timeout" of 60 seconds, which means it will stop trying to download the file after 60 seconds. If you're downloading a large file, you may need to increase the timeout time. (I've set it to 600 seconds below.)

```
options(timeout=600) # 600 seconds to download the file -- default is 60
download.file("https://www2.census.gov/ces/opportunity/county_outcomes.zip", "data/county_outcomes.zip"
options(timeout=60) # Reset the timeout to the default
```

There a couple ways to open up this file. We'll go with a two-step approach of unzipping the file and then reading it in.¹ The code block below shows you how to unzip then read with readr::read_csv.

```
unzip("data/county_outcomes.zip", exdir = "data")
op_atlas <- read_csv("data/county_outcomes.csv")
file.remove("data/county outcomes.csv") # Remove the CSV</pre>
```

That probably took a while to load! That's cause it is a big file. Let's shrink it down to just the necessary variables and rows to save space. Today we're only mapping the mean household income percentile rank of children born to parents at the

¹If you're curious about reading in the file directly from the zip file, check the Data Tips notes.

25th and 75th percentile for a few race groups in Maine. So let's select and filter.

If you checkout the codebook, you can see that variables have the form [outcome]_[race]_[gender]_p[pctile]. We want the outcome of average household income for children born to parents at the 25th percentile and 75th percentile. Per the codebook:

- kfr: Average household income percentile rank of children
- p25: Raised at the 25th percentile
- pooled: Pooled across all races/genders
- state : State fips code
- county : County fips code

A quick Google search confirms that Maine's FIPS code is 23.

Quick comprehension test:

- How do I select a variable for mean percentile rank of white people born in the 25th percentile?
- Is the variable kfr_p25 a valid variable?

Armed with that knowledge, we can carefully select the groups we want and rename to simplify the variable names.

```
op_atlas <- select(op_atlas, czname, state, county,
    kfr_p25 = kfr_pooled_pooled_p25,
    kfr_p75 = kfr_pooled_pooled_p75) %>%
    filter(state==23) # Maine's fips code is 23!
write_csv(op_atlas, "data/county_outcomes_p25_p75.csv") # Save the file
```

By shrinking down the file, we've made it much easier to work with. This is a good practice in general then you only have to get the big data open once.

The last thing we'll need to do is to create a 5-digit FIPS code for each county by combining the state and county codes. This is a common practice in the US for uniquely identifying counties.

We'll use this to join the Opportunity Atlas data with Maine county shapefiles on the variable, GEOID, which is the FIPS code as a character variable. Below I create a character variable called GEOID that contains the 5-digit FIPS code.

```
op_atlas <- op_atlas %>%
    mutate(GEOID= as.character(state*1000+county)) # Create a 5-digit FIPS code as a string
```

Introduction: CRS and map projections

If you're reading this after the fact, I recommend these two helpful resources. The very short version is that spatial data, like all coordinate-based systems, only make sense relative to some fixed point. That fixed point is what the Coordinate Reference Systems, or **CRS**, is trying to set. In R, we can define the CRS in one of two ways:

- 1. EPSG code (e.g. 3857), or
- 2. PROJ string (e.g. "+proj=merc").

We'll see examples of both implementations in in this lecture. For the moment, however, just know that they are equally valid ways of specifying CRS in R (albeit with different strengths and weaknesses). You can search for many different CRS definitions here.

Aside: There are some important updates happening in the world of CRS and geospatial software, which will percolate through to the R spatial ecosystem. Thanks to the hard work of various R package developers, these behind-the-scenes changes are unlikely to affect the way that you interact with spatial data in R. But they are worth understanding if you plan to make geospatial work a core component of your research. More here.

Similarly, whenever we try to plot (some part of) the earth on a map, we're effectively trying to **project** a 3-D object onto a 2-D surface. This will necessarily create some kind of distortion. Different types of map projections limit distortions for

some parts of the world at the expense of others. For example, consider how badly the standard (but infamous) Mercator projection distorts the high latitudes in a global map (source):

Sorry, this GIF is only available in the the HTML version of the notes.

Bottom line: You should always aim to choose a projection that best represents your specific area of study. I'll also show you how you can "re-orient" your projection to a specific latitude and longitude using the PROJ syntax. But first I'm obliged to share this XKCD summary. (Do yourself a favour and click on the link.)

Simple Features and the sf package

R has long provided excellent support for spatial analysis and plotting (primarily through the **sp**, **rgdal**, **rgeos**, and **raster** packages). However, until recently, the complex structure of spatial data necessitated a set of equally complex spatial objects in R. I won't go into details, but a spatial object (say, a SpatialPolygonsDataFrame) was typically comprised of several "layers" — much like a list — with each layer containing a variety of "slots". While this approach did (and still does) work perfectly well, the convoluted structure provided some barriers to entry for newcomers. It also made it very difficult to incorporate spatial data into the tidyverse ecosystem that we're familiar with. Luckily, all this has changed thanks to the advent of the **sf** package (link).

The "sf" stands for simple features, which is a simple (ahem) standard for representing the spatial geometries of real-world objects on a computer.² These objects — i.e. "features" — could include a tree, a building, a country's border, or the entire globe. The point is that they are characterised by a common set of rules, defining everything from how they are stored on our computer to which geometrical operations can be applied them. Of greater importance for our purposes, however, is the fact that **sf** represents these features in R as *data frames*. This means that all of our data wrangling skills from previous lectures can be applied to spatial data; say nothing of the specialized spatial functions that we'll cover next.

Somewhat confusingly, most of the functions in the **sf** package start with the prefix st_{-} . This stands for *spatial and temporal* and a basic command of this package is easy enough once you remember that you're probably looking for $st_{SOMETHING}()$.³

Reading in spatial data

Vector-based spatial data is often stored in a shapefile, which is a file format for storing the geometric location and attribute information of geographic features. Rather than explain a shapefile, let's just read one in and see what it looks like. Where can we get shapefiles? Why from the Census!

The Census Bureau maintains a database of shapefiles for all kinds of geographic entities, from states to counties to census tracts. You can download these shapefiles from the TIGER (Topologically Integrated Geographic Encoding and Referencing) website. Alternatively, you can use the **tidycensus** (or **tigris** explained below) package to download them for you by setting geometry=TRUE as an argument in functions like tidycensus::get_acs().

Let's demonstrate by reading in a shapefile for Maine. As you might have guessed, we're going to use the st_read() command and **sf** package will handle all the heavy lifting behind the scenes. Shapefile are a "geospatial vector data format" that is widely used in GIS software that typically have the file ending . shp.⁴ Basically, it contains the shape of each feature (e.g. county) represented as coordinates, along with a bunch of other information about the feature (e.g. county name, population, etc.).

```
me = tidycensus::get_acs(
  geography = "county",
  variables = "B01001_001", # Population size variable
  state = "ME",
  geometry = TRUE,
  year=2010 # Opp Atlas data uses 2010 county boundaries
)
```

²See the first of the excellent **sf** vignettes for more details.

 $^{^{3}}$ I rather wish they'd gone with a sf_ prefix myself — or at least created aliases for it — but the package developers are apparently following standard naming conventions from PostGIS.

⁴See here for more details.

Now we can see the explicit data frame structure. The object has the familiar tibble-style output that we're used to (e.g. it only prints the first 10 rows of the data). However, it also has some additional information in the header, like a description of the geometry type ("MULTIPOLYGON") and CRS (e.g. EPSG ID 4267). One thing I want to note in particular is the geometry column right at the end of the data frame. This geometry column is how **sf** package achieves much of its magic: It stores the geometries of each row element in its own list column.⁵ Since all we really care about are the key feature attributes — county name, FIPS code, population size, etc. — we can focus on those instead of getting bogged down by hundreds (or thousands or even millions) of coordinate points. In turn, this all means that our favourite **tidyverse** operations and syntax (including the pipe operator %>%) can be applied to spatial data. Let's review some examples, starting with plotting.

Concept check: What clean code principle is the **sf** package following by storing the geometries in their own list column?

Plotting and projection with ggplot2

Plotting **sf** objects is incredibly easy thanks to the package's integration with both base R plot() and **ggplot2**. I'm going to focus on the latter here, but feel free to experiment.⁶ The key geom to remember is geom_sf(). For example:

```
# library(tidyverse) ## Already loaded
```

```
me_plot =
  ggplot(me) +
  geom_sf(aes(fill = estimate), alpha=0.8, col="white") +
  scale_fill_viridis_c(name = "Population estimate") +
  ggtitle("Counties of Maine")
```

me_plot

⁵For example, we could print out the coordinates needed to plot the first element in our data frame, Lincoln county, by typing me\$geometry[[1]]. In contrast, I invite you to see how complicated the structure of a traditional spatial object is by running, say, str(as(me, "Spatial")).

⁶Plotting **sf** objects with the base **plot** function is generally faster. However, I feel that you give up a lot of control and intuition by moving away from the layered, "graphics of grammar" approach of **ggplot2**.

231 1800019787 +44.9670088 -067.6093542 MULTIPOLYGON (((-5432146 54... STATEFP ## ## 45 23

231 23

Or, we can specify a common projection directly in the ggplot call using coord_sf(). This is often the most convenient approach when you are combining multiple **sf** data frames in the same plot.⁷

06

06

019

029

 $^{^7}$ Note that we used a PROJ string to define the CRS reprojection below. But we could easily use an EPSG code instead. For example, here's the ME west plane projection, which we could use by setting crs=26984.

Data wrangling with dplyr and tidyr

The tidyverse approach to data wrangling carries over very smoothly to **sf** objects. For example, the standard **dplyr** verbs like filter(), mutate() and select() all work.

Be sure to run the code in this block to split NAME into the COUNTY and STATE components.

```
me %>%
  separate(NAME,c('COUNTY','STATE'),sep = ", ") %>%
 filter(COUNTY %in% c("Sagadahoc County", "Androscoggin County", "Cumberland County")) %>%
  mutate(estimate_div_1000 = estimate/1000) %>% # Estimate in 1000s
  select(-variable,-moe) # Drop the variable and margin of error columns
## Simple feature collection with 3 features and 5 fields
## Geometry type: MULTIPOLYGON
## Dimension:
                  XY
## Bounding box:
                  xmin: -70.86658 ymin: 43.52726 xmax: -69.6888 ymax: 44.48722
## Geodetic CRS:
                  NAD83

me <- me %>% separate(NAME,c('COUNTY','STATE'),sep = ", ") # Keeping this one
```

You can also perform group_by() and summarise() operations as per normal (see here for a nice example). Furthermore, the **dplyr** family of join functions also work, which can be especially handy when combining different datasets by FIPS code or some other *attribute*. **However, this presumes that only one of the objects has a specialized geometry column.** In other words, it works when you are joining an **sf** object with a normal data frame. In cases where you want to join two **sf** objects based on their *geometries*, there's a specialized st_join() function. I provide an example of this latter operation in the section on geometric operations below.

Let's try this by joining on Maine's Opportunity Atlas county level data, which we read in and processed earlier.

```
ggplot(me_join) +
  geom_sf(aes(fill = kfr_p25), alpha=0.8, col="white") +
  scale_fill_viridis_c(name = "Average income percentile") +
  ggtitle("Average income percentile for children raised at 25th percentile")
```

me_join <- inner_join(me,op_atlas, by="GEOID")</pre>

Average income percentile for children raised at 25th percentile

And, just to show that we've got the bases covered, you can also implement your favourite **tidyr** verbs. For example, we can tidyr::gather() the data to long format, which is useful for facetted plotting.⁸ Here I demonstrate this by plotting the average income percentile of children born to parents at the 25th percentile and 75th percentile.

```
me_join %>%
select(GEOID, kfr_p25, kfr_p75, geometry) %>%
pivot_longer(cols=c(kfr_p25,kfr_p75), names_to='parent_ptile',names_prefix = 'kfr_p',values_to='kfr')
```

⁸In case you're wondering: the newer tidyr::pivot_* functions do not yet work with **sf** objects.

```
mutate(kfr=kfr*100, # put in percent terms
    parent_ptile=paste0('Raised at ',parent_ptile,'th percentile')) %>% # Make the parent_ptile variab
ggplot() +
geom_sf(aes(fill = kfr), alpha=0.8, col="white") +
scale_fill_viridis_c(name = "Average income percentile rank") +
facet_wrap(~parent_ptile, ncol = 2) +
labs(title = "Mean income percentile of children born to parents at the 25th percentile") +
theme(legend.position="bottom")
```

On your problem set, you'll have to do something similar at the Census tract level and by race, so take note.

Specialized geometric operations

Alongside all the tidyverse functionality, the **sf** package comes with a full suite of geometrical operations. You should take a look at at the third **sf** vignette or the *Geocomputation with R* book to get a complete overview.

There are two types of operations: **unary** and **binary** shown below. These categories are helpful to keep in mind when you're trying to find a function to do something new, but you can still get pretty far without memorizing them.

Here are a few examples to get you started:

Unary operations So-called *unary* operations are applied to a single object. For instance, you can unite sub-elements of an **sf** object (e.g. counties) into larger elements (e.g. states) using sf::st_union():

```
me %>%
st_union() %>%
ggplot() +
geom_sf(fill=NA, col="black") +
labs(title = "Outline of Maine")
```

Or, you can get the st_area(), st_centroid(), st_boundary(), st_buffer(), etc. of an object using the appropriate command. For example:

me %>% st_area() %>% head(5) ## Only show the area of the first five counties to save space.

```
## Units: [m^2]
## [1] 9191355157 8418644946 17637152538 6060468737 4506281023
And:
me_centroid = st_centroid(me)
ggplot(me) +
  geom_sf(fill = "black", alpha = 0.8, col = "white") +
  geom_sf(data = me_centroid, col = "red") + ## Notice how easy it is to combine different sf objects
  labs(
    title = "Counties of Maine",
    subtitle = "Centroids in red"
    )
```

Binary operations Another set of so-called *binary* operations can be applied to multiple objects. So, we can get things like the distance between two spatial objects using sf::st_distance(). In the below example, I'm going to get the distance from Androscoggin county to York county, as well as itself. The latter is just a silly addition to show that we can easily make multiple pairwise comparisons, even when the distance from one element to another is zero.

```
andro_york = me %>% filter(COUNTY %in% c("Androscoggin County", "York County"))
andro = me %>% filter(COUNTY %in% c("Androscoggin County"))
ay_dist = st_distance(andro_york, andro)
## We can use the `units` package (already installed as sf dependency) to convert to kilometres
ay_dist = ay_dist %>% units::set_units(km) %>% round()
ggplot(me) +
geom_sf(fill = "black", alpha = 0.8, col = "white") +
geom_sf(data = andro_york, aes(fill = COUNTY), col = "white") +
labs(
```

```
title = "Calculating distances",
subtitle = paste0("The distance between Androscoggin and Cumberland is ", ay_dist[2], " km")
) +
theme(legend.title = element_blank())
```

Binary logical operations A sub-genre of binary geometric operations falls into the category of logic rules — typically characterising the way that geometries relate in space. (Do they overlap, are they nearby, etc.)

For example, we can calculate the intersection of different spatial objects using sf::st_intersection(). For this next example, I'm going to use the primary roads spatial object from the **tigris** package. Don't worry too much about the process used for loading these datasets; I'll cover that in more depth shortly. For the moment, just focus on the idea that we want to see which counties are intersected by the river network.

First, I want to make sure the roads have the same projection as maine using the st_crs() package.

```
road = tigris::primary_roads()
## Make sure they have the same projection
road = st transform(road, crs = st crs(me))
```

Second, let me plot all the data to see what we're working with.

```
ggplot() +
geom_sf(data = me, alpha = 0.8, fill = "white", col = "black") +
geom_sf(data = road, col = "red", lwd = 1) +
labs(
    title = "States of the US",
    subtitle = "Also showing the US road network"
    )
```

```

```

Note that st_intersection() only preserves *exact* points of overlap. As in, this is the exact path that the road follow within these regions. We can see this more explicitly in map form:

```
me_intersected %>%
ggplot() +
geom_sf(alpha = 0.8, aes(fill = FULLNAME, col = FULLNAME)) +
labs(
    title = "Maine road system",
    caption = "Colours depict each road"
    ) +
    theme(legend.title = element_blank())
```

Maine road system

```
If we instead wanted to plot the intersected counties (i.e. keeping their full geometries), we have a couple options. We could filter the me object by matching its region IDs with the me_intersected object. However, a more direct option is to use the sf::st_join() function which matches objects based on overlapping (i.e. intersecting) geometries<sup>9</sup>:
```

```
# Select only the road variables
st_join(me,road,left=FALSE) %>% # left=FALSE means we keep only the intersected geometries
ggplot() +
```

⁹The function st_filter() is more efficient, but has less functionality. So I am teaching you st_join.

```
geom_sf(alpha = 0.8, fill = "black", col = "gray50") +
geom_sf(data = me_intersected, col = "#05E9FF", lwd = 1) +
labs(title = "Counties with primary roads only")
```

Counties with primary roads only

Bordering counties

Did you note above that we used st_join to find the intersected counties? Let's do that to get bordering counties!

```
st_join(me,andro,left=FALSE) %>%
ggplot() +
geom_sf(alpha = 0.8, fill = "black", col = "gray50") +
labs(title = "Androscoggin County and its Neighbors")
```

But what if we wanted to leave out Androscoggin? We tell st_join that we want to join using the st_touches predicate to only show the counties that touch Androscoggin.

```
st_join(me,andro,left=FALSE,join=st_touches) %>% # Note the new predicate!
ggplot() +
geom_sf(alpha = 0.8, fill = "black", col = "gray50") +
#geom_sf(data = andro, col = "red",fill='red', lwd = 1) + # Highlight androscoggin
labs(title = "Androscoggin County and its Neighbors")
```

Wait, what's going on? How did we drop Androscoggin? st_touches is a predicate that returns TRUE if the geometries have at least one point in common, but their interiors do not intersect. In other words, it returns TRUE if the geometries are adjacent. Let's visualize that:

st_join(me,andro,left=FALSE,join=st_touches)

```

Note the .x and the .y because the column names overlapped. R uses .x and .y to distinguish between the two objects' columns.¹⁰

If you just wan to subset down, you can use st_filter() to accomplish the same task. By default st_filter() returns the intersection, but the argument .predicate can be used to specify a different operation like st_touches like join in st_join.

st_filter(me,andro, .predicate = st_touches)

```

Comprehension check Why would you want know the neighboring counties of a given county?

Nearest neighbors

Sometimes you'll want to know more than neighbors, you'll want to know the nearest k neighbors, where k is some arbitrary number. Consider this plot:

knitr::include_graphics("../09-oppatlas/pics/spatial_correlation_decay.png")

This is plots the spatial correlation of income mobility with poverty for neighboring census tracts. The spatial correlation is highest within group, but then decays.

It is possible to do this using the **sf** package using the **st_nearest_feature()** function to get the nearest feature and then repeating to get the next most nearest and so on. A for loop or some **purrr** magic (covered later) and you're off to the races. But it turns out, there's a package that makes this easier: **nngeo** and its functions **st_nn** for "nearest neighbors."

```
st_nn(andro, # The object to find the nearest neighbors for
  me, # The object to find the nearest neighbors in
```

lines or polygons ## ## [[1]] ## [1] 1 3 4 st_join(me, me, join = st_nn, # Use st_nn k = 5, # The number of nearest neighbors maxdist=100000) # The max distance in meters to look for neighbors ## lines or polygons ## ## Simple feature collection with 80 features and 12 fields ## Geometry type: MULTIPOLYGON ## Dimension: XY ## Bounding box: xmin: -71.08433 ymin: 42.97776 xmax: -66.9499 ymax: 47.45969 ## Geodetic CRS: NAD83 **##** First 10 features: ## GEOID.x COUNTY.x STATE.x variable.x estimate.x moe.x GEOID.y ## 1 23001 Androscoggin County Maine B01001 001 107882 NA 23001 ## 1.1 23001 Androscoggin County Maine B01001_001 107882 NA 23005 ## 1.2 23001 Androscoggin County Maine B01001_001 107882 NΑ 23007 ## 1.3 23001 Androscoggin County Maine B01001_001 107882 NA 23011 ## 1.4 23001 Androscoggin County Maine B01001_001 107882 NA 23017 ## 2 23003 Aroostook County Maine B01001_001 72412 NA 23003 ## 2.1 23003 Maine B01001 001 Aroostook County 72412 NΑ 23019 ## 2.2 23003 Aroostook County Maine B01001 001 72412 NA 23021 ## 2.3 23003 Aroostook County Maine B01001 001 72412 NA 23025 ## 2.4 23003 Aroostook County Maine B01001_001 72412 NA 23029 ## COUNTY.y STATE.y variable.y estimate.y moe.y Maine B01001 001 ## 1 Androscoggin County 107882 NA ## 1.1 Cumberland County Maine B01001 001 279994 NA ## 1.2 Franklin County Maine B01001_001 30657 NA ## 1.3 Kennebec County Maine B01001_001 121925 NA ## 1.4 Oxford County Maine B01001_001 57867 NA ## 2 Aroostook County Maine B01001_001 72412 NA ## 2.1 Penobscot County Maine B01001 001 152934 NA ## 2.2 Piscataquis County Maine B01001_001 17555 NA ## 2.3 Somerset County Maine B01001_001 52261 NA ## 2.4 Maine B01001_001 Washington County 33154 NA ## geometry ## 1 MULTIPOLYGON (((-70.16011 4... ## 1.1 MULTIPOLYGON (((-70.16011 4... ## 1.2 MULTIPOLYGON (((-70.16011 4... ## 1.3 MULTIPOLYGON (((-70.16011 4... ## 1.4 MULTIPOLYGON (((-70.16011 4... ## 2 MULTIPOLYGON (((-68.5918 47... ## 2.1 MULTIPOLYGON (((-68.5918 47... ## 2.2 MULTIPOLYGON (((-68.5918 47... ## 2.3 MULTIPOLYGON (((-68.5918 47...

T

k=3) # The number of nearest neighbors

2.4 MULTIPOLYGON (((-68.5918 47...

This returns the five nearest neighbors to each county including itself.

That's about as much **sf** functionality as I can show you for today. The remaining part of this lecture will cover some additional mapping considerations and some bonus spatial R "swag". However, I'll try to slip in a few more **sf**-specific operations along the way.

BONUS 1: Where to get map data

As our first Maine examples demonstrate, you can easily import external shapefiles, KML files, etc., into R. Just use the generic sf::st_read() function on any of these formats and the **sf** package will take care of the rest. However, we've also seen with the France example that you might not even need an external shapefile. Indeed, R provides access to a large number of base maps — e.g. countries of the world, US states and counties, etc. — through the **maps**, (higher resolution) **mapdata** and **spData** packages, as well as a whole ecosystem of more specialized GIS libraries.¹¹ To convert these maps into "**sf**-friendly" data frame format, we can use the sf::st_as_sf() function as per the below examples.

Example 1: The World

```
# library(maps) ## Already loaded
world = st_as_sf(map("world", plot = FALSE, fill = TRUE))
world_map =
  ggplot(world) +
  geom_sf(fill = "grey80", col = "grey40", lwd = 0.3) +
  labs(
    title = "The world",
    subtitle = paste("EPSG:", st_crs(world)$epsg)
    )
world_map
```

The world

EPSG: NA

¹¹The list of specialised maps packages is far too long for me to cover here. You can get marine regions, protected areas, nightlights, ..., etc., etc.

All of the usual **sf** functions and transformations can then be applied. For example, we can reproject the above world map onto the Lambert Azimuthal Equal Area projection (and further orientate it at the South Pole) as follows.

```
world_map +
    coord_sf(crs = "+proj=laea +y_0=0 +lon_0=155 +lat_0=-90") +
    labs(subtitle = "Lambert Azimuthal Equal Area projection")
```

The world

Lambert Azimuthal Equal Area projection

Several digressions on projection considerations

Winkel tripel projection As we've already seen, most map projections work great "out of the box" with **sf**. One niggling and notable exception is the Winkel tripel projection. This is the preferred global map projection of *National Geographic* and requires a bit more work to get it to play nicely with **sf** and **ggplot2** (as detailed in this thread). Here's a quick example of how to do it:

```
# library(lwgeom) ## Already loaded
wintr_proj = "+proj=wintri +datum=WGS84 +no_defs +over"
world_wintri = lwgeom::st_transform_proj(world, crs = wintr_proj)
## Don't necessarily need a graticule, but if you do then define it manually:
gr =
    st_graticule(lat = c(-89.9,seq(-80,80,20),89.9)) %>%
    lwgeom::st_transform_proj(crs = wintr_proj)
ggplot(world_wintri) +
    geom_sf(data = gr, color = "#cccccc", size = 0.15) + ## Manual graticule
    geom_sf(fill = "grey80", col = "grey40", lwd = 0.3) +
    coord sf(datum = NA) +
```

```
theme_ipsum(grid = F) +
labs(title = "The world", subtitle = "Winkel tripel projection")
```

The world

Winkel tripel projection

Equal Earth projection The latest and greatest projection, however, is the "Equal Earth" projection. This *does* work well out of the box, in part due to the ne_countries dataset that comes bundled with the **rnaturalearth** package (link). I'll explain that second part of the previous sentence in moment. But first let's see the Equal Earth projection in action.

```
# library(rnaturalearth) ## Already loaded
```

```
countries =
  ne_countries(returnclass = "sf") %>%
  st_transform(8857) ## Transform to equal earth projection
  # st_transform("+proj=eqearth +wktext") ## PROJ string alternative
ggplot(countries) +
  geom_sf(fill = "grey80", col = "grey40", lwd = 0.3) +
  labs(title = "The world", subtitle = "Equal Earth projection")
```

The world Equal Earth projection

Pacfic-centered maps and other polygon mishaps As noted, the rnaturalearth::ne_countries spatial data frame is important for correctly displaying the Equal Earth projection. On the face of it, this looks pretty similar to our maps::world spatial data frame from earlier. They both contain polygons of all the countries in the world and appear to have similar default projections. However, some underlying nuances in how those polygons are constructed allows us avoid some undesirable visual artefacts that arise when reprojecting to the Equal Earth projection. Consider:

```
world %>%
st_transform(8857) %>% ## Transform to equal earth projection
ggplot() +
geom_sf(fill = "grey80", col = "grey40", lwd = 0.3) +
labs(title = "The... uh, world", subtitle = "Projection fail")
```

The... uh, world Projection fail

These types of visual artefacts are particularly common for Pacific-centered maps and, in that case, arise from polygons extending over the Greenwich prime meridian. It's a suprisingly finicky problem to solve. Even the **rnaturalearth** doesn't do a good job. Luckily, Nate Miller has you covered with an excellent guide to set you on the right track.

Example 2: A single country (i.e. Norway)

The **maps** and **mapdata** packages have detailed county- and province-level data for several individual nations. We've already seen this with France, but it includes the USA, New Zealand and several other nations. However, we can still use it to extract a specific country's border using some intuitive syntax. For example, we could plot a base map of Norway as follows.

```
norway = st_as_sf(map("world", "norway", plot = FALSE, fill = TRUE))
## For a hi-resolution map (if you *really* want to see all the fjords):
# norway = st_as_sf(map("worldHires", "norway", plot = FALSE, fill = TRUE))
norway %>%
ggplot() +
geom_sf(fill="black", col=NA)
```

Hmmm. Looks okay, but I don't really want to include non-mainland territories like Svalbaard (to the north) and the Faroe Islands (to the east). This gives me the chance to show off another handy function, sf::st_crop(), which I'll use to crop our **sf** object to a specific extent (i.e. rectangle). While I am at, we could also improve the projection. The Norwegian Mapping Authority recommends the ETRS89 / UTM projection, for which we can easily obtain the equivalent EPSG code (i.e. 25832) from this website.

```
norway %>%
st_crop(c(xmin=0, xmax=35, ymin=0, ymax=72)) %>%
st_transform(crs = 25832) %>%
ggplot() +
geom_sf(fill="black", col=NA)
```

There you go. A nice-looking map of Norway. Fairly appropriate that it resembles a gnarly black metal guitar.

Aside: I recommend detaching the **maps** package once you're finished using it, since it avoids potential namespace conflicts with purrr::map.

detach(package:maps) ## To avoid potential purrr::map() conflicts

BONUS 2: More on US Census data with tidycensus and tigris

Note: Before continuing with this section, you will first need to request an API key from the Census.

Working with Census data has traditionally quite a pain. You need to register on the website, then download data from various years or geographies separately, merge these individual files, etc. Thankfully, this too has recently become much easier thanks to the Census API and — for R at least — the **tidycensus** (link) and **tigris** (link) packages from Kyle Walker (a UO alum). This next section will closely follow a tutorial on his website.

We start by loading the packages and setting our Census API key. Note that I'm not actually running the below chunk, since I expect you to fill in your own Census key. You only have to run this function once.

```
# library(tidycensus) ## Already loaded
# library(tigris) ## Already loaded
## Replace the below with your own census API key. We'll use the "install = TRUE"
## option to save the key for future use, so we only ever have to run this once.
census_api_key("YOUR_CENSUS_API_KEY_HERE", install = TRUE)
## Also tell the tigris package to automatically cache its results to save on
## repeated downloading. I recommend adding this line to your ~/.Rprofile file
## so that caching is automatically enabled for future sessions. A quick way to
```

```
## do that is with the `usethis::edit_r_profile()` function.
options(tigris_use_cache=TRUE)
```

Let's say that our goal is to provide a snapshot of Census rental estimates across different cities in the Pacific Northwest. We start by downloading tract-level rental data for Oregon and Washington using the tidycensus::get_acs() function. Note that you'll need to look up the correct ID variable (in this case: "DP04_0134").

```
rent =
  tidycensus::get_acs(
    geography = "tract", variables = "DP04_0134",
    state = c("WA", "OR"), geometry = TRUE
    )
```

```
rent
```

```

This returns an **sf** object, which we can plot directly.

```
rent %>%
ggplot() +
geom_sf(aes(fill = estimate, color = estimate)) +
coord_sf(crs = 26910) +
scale_fill_viridis_c(name = "Rent ($)", labels = scales::comma) +
scale_color_viridis_c(name = "Rent ($)", labels = scales::comma) +
labs(
    title = "Rental rates across Oregon and Washington",
    caption = "Data: US Census Bureau"
    )
```

Rental rates across Oregon and Washington

Hmmm, looks like you want to avoid renting in Seattle if possible...

The above map provides rental information for pretty much all of the Pacific Northwest. Perhaps we're not interested in such a broad swatch of geography. What if we'd rather get a sense of rents within some smaller and well-defined metropolitan areas? Well, we'd need some detailed geographic data for starters, say from the TIGER/Line shapefiles collection. The good news is that the **tigris** package has you covered here. For example, let's say we want to narrow down our focus and compare rents across three Oregon metros: Portland (and surrounds), Corvallis, and Eugene.

```
or_metros =
  tigris::core_based_statistical_areas(cb = TRUE) %>%
  # filter(GEOID %in% c("21660", "18700", "38900")) %>% ## Could use GEOIDs directly if you know them
  filter(grep1("Portland|Corvallis|Eugene", NAME)) %>%
  filter(grep1("OR", NAME)) %>% ## Filter out Portland, ME
  select(metro_name = NAME)
```

Now we do a spatial join on our two data sets using the sf::st_join() function.

```
or_rent =
  st_join(
    rent,
    or_metros,
    join = st_within, left = FALSE
    )
  or_rent

One useful way to summarize this data and compare across metros is with a histogram. Note that "regular" **ggplot2** geoms and functions play perfectly nicely with **sf** objects (i.e. we aren't limited to geom_sf()).

That's a quick taste of working with **tidycensus** (and **tigris**). In truth, the package can do a lot more than I've shown you here. For example, you can also use it to download a variety of other Census microdata such as PUMS, which is much more detailed. See the **tidycensus** website for more information.

Aside: sf and data.table

sf objects are designed to integrate with a tidyverse workflow. They can also be made to work a data.table workflow too, but the integration is not as slick. This is a known issue and I'll only just highlight a few very brief considerations.

You can convert an sf object into a data.table. But note that the key geometry column appears to lose its attributes.

```

MULTIPOLYGON (((-68.43227 46.03557, -68.43285 4...

MULTIPOLYGON (((-68.80096 44.46203, -68.80007 4...

MULTIPOLYGON (((-70.29383 45.1099, -70.29348 45...

What's the upshot? Well, basically it means that you have to refer to this "geometry" column explicitly whenever you implement a spatial operation. For example, here's a repeat of the st_union() operation that we saw earlier. Note that I explicitly refer to the "geometry" column both for the st_union() operation (which, moreover, takes place in the "j" data.table slot) and when assigning the aesthetics for the ggplot() call.

```
me_dt[, .(geometry = st_union(geometry))] %>% ## Explicitly refer to 'geometry' col
ggplot(aes(geometry = geometry)) + ## And here again for the aes()
geom_sf(fill=NA, col="black") +
labs(title = "Outline of Maine",
subtitle = "This time brought to you by data.table")
```

Outline of Maine

This time brought to you by data.table

Of course, it's also possible to efficiently convert between the two classes — e.g. with as.data.table() and st_as_sf() — depending on what a particular section of code does (data wrangling or spatial operation). I find that often use this approach in my own work.

Further reading

You could easily spend a whole semester (or degree!) on spatial analysis and, more broadly, geocomputation. I've simply tried to give you as much useful information as can reasonably be contained in one lecture. Here are some resources for further reading and study:

- The package websites that I've linked to throughout this tutorial are an obvious next port of call for delving deeper into their functionality: **sf**, **leaflet**, etc.
- The best overall resource right now may be *Geocomputation with R*, a superb new text by Robin Lovelace, Jakub Nowosad, and Jannes Muenchow. This is a "living", open-source document, which is constantly updated by its authors and features a very modern approach to working with geographic data. Highly recommended.
- Similarly, the rockstar team behind **sf**, Edzer Pebesma and Roger Bivand, are busy writing their own book, *Spatial Data Science*. This project is currently less developed, but I expect it to become the key reference point in years to come. Imporantly, both of the above books cover **raster-based** spatial data.
- On the subject of raster data... If you're in the market for shorter guides, Jamie Afflerbach has a great introduction to rasters here. At a slightly more advanced level, UO's very own Ed Rubin has typically excellent tutorial here. Finally, the **sf** team is busy developing a new package called **stars**, which will provide equivalent functionality (among other things) for raster data. **UPDATE:** I ended up caving and wrote up a short set of bonus notes on rasters here.

- If you want more advice on drawing maps, including a bunch that we didn't cover today (choropleths, state-bins, etc.), Kieran Healy's *Data Vizualisation* book has you covered.
- Something else we didn't really cover at all today was **spatial statistics**. This too could be subject to a degree-length treatment. However, for now I'll simply point you to *Spatio-Temporal Statistics with R*, by Christopher Wikle and coauthors. (Another free book!) Finally, since it is likely the most interesting thing for economists working with spatial data, I'll also add that Darin Christensen and Thiemo Fetzer have written a very fast R-implementation (via C++) of Conley standard errors. The GitHub repo is here. See their original blog post (and update) for more details.
